#### Abstract

One of the most important challenges in shared mobility services (e.g., ride-sharing and parcel delivery) is planning routes for workers by considering real road conditions. To tackle this challenge, the "insertion operator", which computes the optimal route for the worker to serve (i.e., insert) the newly appeared delivery request, has been acted as the fundamental operation in existing solutions. However, existing works implicitly assume a static road network, hence are hard to fulfill the real-world scenario, where travel time between two locations is not constant at different times of a day. By contrast, we focus on the insertion operator over time-dependent road networks that capture the periodic pattern of road conditions. We also show that the time complexity of existing solutions would degrade into cubic time and hence such solutions can no longer satisfy the real-time requirement under this real-world setting. To satisfy the need for real-time computation, we propose a data summary to model the time-dependent travel time functions between pairs of vertices in the route. Based on the data summary, we design an efficient solution that can enumerate the best insertion position in linear time while satisfying complex spatiotemporal constraints. Finally, extensive experiments are conducted on real datasets from several applications of shared mobility. The results show that our solution is up to $44.5 \times$ faster than the state-of-the-art solution.

## 1 INTRODUCTION

Shared mobility services [34], such as ride-sharing and food delivery, allow a worker to provide the shared ride for multiple requests with similar traveling schedules. For example, in a ride-sharing platform (e.g., DiDi Chuxing [2]) or a food delivery platform (e.g.,

Meituan [4]), a worker (e.g., a driver or courier) can carry more than one passenger or food parcel that have similar origins and destinations. Finding a proper and practical route in real-time for a worker to serve a newly appeared request is one of the most significant challenges in these platforms, especially during peak hours when the number of requests is large-scale.

In the past years, planning routes in shared mobility has been widely studied $[8,12,13,19,22,23,26,32-34,36,41,42,47-49]$. Most of these solutions are built upon a frequently-used operator called insertion. This operator aims to find the optimal route with the minimum increased travel time to serve (or attempt to serve) a newly appeared request for a worker on the real-world road network. The route is identified immediately when the request appears on the platform. In real industry, more than one worker is on the way to serve the new request, and the one, who takes the minimum increased travel time to deliver it before the deadline, will be allocated to the request [28, 41]. When no worker is close enough, the request may need to wait for some time until being served or canceled. Prior studies [35, 39] have demonstrated that the insertion operator with low time complexity (e.g., linear time) can reduce the efficiency bottleneck by a large margin.

(a) Static road networks case.

(b) Real road networks case.

Figure 3: Calculate the new arrival time at $d_{2}$.
Motivation. Despite extensive research on optimizing the insertion operator, existing solutions still remain a challenging obstacle to be deployed in real-world applications, i.e., a common and implicit assumption on the static road network. In other words, these solutions all fail to consider the dynamic nature of road conditions that are affected by weather, traffic congestion, etc. Unfortunately, when considering this real-world factor, we find that their solutions will either produce infeasible routes or significantly increase the time complexity. Here, we take an example to explain this finding as follows.

Motivation Example. Fig. 1a shows an example that the shortest travel time between any two locations is not constant on a realworld road network. For instance, Google Map [3] shows the travel time of a single route at different times in the morning, i.e., 12 minutes at 8:10 am and 14 minutes at 8:20 am. This delay is due to the peak hours of the daily traffic. In fact, the travel time of this route periodically varies between 12 and 22 minutes every day. Thus, planning a practical route in shared mobility needs to consider the dynamic nature of road networks.

Due to this reason, it is non-trivial to study the insertion operator over time-dependent road networks that are commonly used to model real-world city networks [9, 37, 38]. Fig. 1b shows an example of inserting a new request on a real-world road network. Suppose a taxi driver is traveling from the location $o_{1}$ to the location $d_{1}$ to serve two passengers, where $o_{1}-o_{2}$ are the passengers' origins and $d_{1}-d_{2}$ are the passengers' destinations. At some time, the third passenger $r_{3}$ submits his ride-sharing request to the platform, and the insertion operation is used to compute the minimum increased travel time for this worker to additionally serve the newly appeared request with the origin $o_{3}$ and the destination $d_{3}$.

The insertion operation considers $O\left(n^{2}\right)$ pairs of positions to insert the new request's origin and destination into the current route, where $n$ is the number of locations in the current route. The value of $n$ can be more than 30 in real-world applications according to a recent statistic report [7]. One possible pair ( 1,3 ), which inserts $o_{3}$ between $o_{1}$ and $o_{2}$ and $d_{3}$ between $d_{2}$ and $d_{1}$, causes two detours marked by dashed arrows, is as shown in Fig. 2b. For this case, existing solutions calculate the increased travel time by adding up the travel time of these detours. Although such an additivity property can be established in a static road network, it no longer holds in a real-world road network. For instance, after inserting $o_{3}$ at position 1 , directly adding up the delay time (i.e., $\operatorname{dis}\left(o_{1}, o_{3}\right)+\operatorname{dis}\left(o_{3}, o_{2}\right)$ at $8: 10 \mathrm{am}, \operatorname{dis}()$ is the static shortest travel time) of detours to get the new arrival time at $d_{2}$, while sequentially querying the delay time at each location based on the new route is query $\left(o_{2}, d_{2}\right.$, query $\left(o_{3}, o_{2},\left(q u e r y\left(o_{1}, o_{3}, \operatorname{arr}\left[o_{1}\right]\right)\right)\right)$ ) (the function

Table 1: Summary of major notations.

| Notation | Description |
| :---: | :---: |
| $G(V, E, F)$ | time-dependent road network |
| $f_{i, j}(t)$ | $f_{i, j} \in F$ weight function of edge $e_{i, j} ;$ |
| $f_{x, y}^{\prime}(t)$ | weight function of the route from $v_{x}$ to $v_{y}$ |
| $n$ | number of locations a worker visits to serve assigned requests |
| query $(u, v, t)$ | shortest arrival time query over $G(V, E, F)$ |
| ComTravel $(u, v, t)$ | compound travel function over route $u$ to $v$ |
| $v_{w}, c_{w}$ | location and capacity of worker $w$ |
| $o_{r}, d_{r}$ | origin and destination of request $r$ |
| pik $\left(o_{r}\right), \operatorname{del}\left(d_{r}\right)$ | pickup time and delivery time of request $r$ |
| $\operatorname{arr}\left[v_{k}\right]$ | arrival time at $v_{k}$ along the route of worker |
| num $\left[v_{k}\right]$ | number of picked request at $v_{k}$ along the route of worker |
| latest $\left[v_{k}\right]$ | the latest arrival time at $v_{k}$ to keep feasibility of the route |
| opt $\left[v_{k}\right]$ | the optimal $i$ value when insert $d_{r}$ before $v_{k}$ |

query () is the shortest arrival time query over real road networks, see Fig. 3 for details). Thus, the additivity property leads to an inaccurate travel time, which could delay the passenger's original trip and significantly hurt user experiences. Similar counter-examples can be easily found in real life [41, 42].
Our Solution Summary. Motivated by this limitation, we study the insertion operator for route planning in shared mobility on time-dependent road networks that are commonly used to model the dynamic nature of road conditions (Sec. 2.1 for more details). To meet the optimality and real-time requirements, we first observe that the key point to hinder the efficiency is how to efficiently answer a spatiotemporal query, i.e., delay time query (delayquery()). To rapidly process the query, we design a data summary called compound travel functions to capture the travel time between locations in the route. By utilizing this data structure, we propose an efficient solution to improve the time complexity from $O\left(n^{3}\right)$ to $O(n)$.
Contribution. The main contributions are listed as follows:

- We are the first to study the insertion operation for route planning in shared mobility on time-dependent road networks.
- We identify that existing solutions to the insertion operations over static road networks cannot always retain the optimal result under the setting of road networks. In our experiments, it could delay $27 \%$ requests' trips.
- To address this limitation, we design an efficient solution by utilizing a novel data summary. We also prove that our solution only takes linear time to compute the exact result, which is no higher than that of existing work.
- Extensive experiments on real datasets from various applications demonstrate that our solution can accelerate the insertion operation by up to $44.5 \times$ in the running time.

Roadmap. The rest of this paper is organized as follows. We first present the problem statement in Sec. 2. Then, our method is elaborated in Sec. 3 and evaluated in Sec. 4. Finally, we review the related work in Sec. 5 and conclude in Section Sec. 6.

## 2 PROBLEM STATEMENT AND BASELINE METHOD

This section introduces the basic concepts (Sec. 2.1), formal problem definition (Sec. 2.2), and exact baseline method (Sec. 2.3). The major notations are summarized in Table 1.

### 2.1 Basic Concepts

Definition 1 (Time-dependent Road Network). A directed graph $G(V, E, F)$ is used to model the real-world road network. Here, $V$ is the set of vertices and each vertex $v \in V$ represents one geolocation. $E \subseteq V \times V$ is the set of edges. Each directed edge $(u, v) \in E$ is associated with a non-negative weight function $f_{u, v}(t) \in F$, where $t$ is the departure time, and $f_{u, v}(t)$ denotes the travel time to the vertex $v$ when departing from the vertex $u$ at time $t$. Besides, for any two vertices $u, v \in V$, the function $q u e r y(u, v, t)$ denotes the shortest arrival time to $v$ when departing from $u$ at time $t$.

Following the conventions in Ref. [9, 37, 38], we adopt piecewise linear functions (PLF) to model the weight functions in road networks, any continuous function of the weight edges can be approximated by a set of such functions [10,31]. Specifically, the function $f_{u, v}(t)$ associated with each directed edge $(u, v) \in E$ is modelled as a set of interpolation points $P=\left\{\left(t_{1}, w_{1}\right),\left(t_{2}, w_{2}\right), \ldots,\left(t_{k}, w_{k}\right)\right\}$, and each point $\left(t_{i}, w_{i}\right)$ denotes that it takes $w_{i}$ unit time to travel from $u$ to $v$ at time $t_{i}$. Besides, a straight line connected two successive points $\left(t_{i}, w_{i}\right),\left(t_{i+1}, w_{i+1}\right)$ fits the linear function in the time domain $\left[t_{i}, t_{i+1}\right)$. For example, if a worker departs from $u$ at time $t \in\left[t_{1}, t_{2}\right)$, his travel time can be calculated as $f_{u, v}(t)=w_{1}+\left(t-t_{1}\right) \frac{w_{2}-w_{1}}{t_{2}-t_{1}}$. Then, the weight function of $(u, v)$ can be formalized by Eq. (1).

$$
f_{u, v}(t)= \begin{cases}w_{1}+\left(t-t_{1}\right) \frac{w_{2}-w_{1}}{t_{2}-t_{1}}, & t_{1} \leq t<t_{2}  \tag{1}\\ w_{2}+\left(t-t_{2}\right) \frac{w_{3}-w_{2}}{t_{3}-t_{2}}, & t_{2} \leq t<t_{3} \\ \cdots & \\ w_{k-1}+\left(t-t_{k-1}\right) \frac{w_{k}-w_{k-1}}{t_{k}-t_{k-1}}, & t_{k-1} \leq t \leq t_{k}\end{cases}
$$

where the time domain of the function $f_{u, v}(t)$ is $\left[t_{1}, t_{k}\right]$.
Property of Time-dependent Road Networks. In the real world, if two people move from $u$ to $v$ at different times, the one who departs earlier usually arrives at $v$ no later than the other one. This phenomenon is summarized as one important property by existing work [9, 37, 38], i.e., the first-in-first-out (FIFO) property. This property implies $t_{1}+f_{u, v}\left(t_{1}\right) \leq t_{2}+f_{u, v}\left(t_{2}\right)$ for any weight function $f_{u, v}(t) \in F$ and departure time $t_{1} \leq t_{2}$.

Based on Definition 1 and the conventions of existing work [18, 21, 27, 34, 35], we present the definitions of other basic concepts, including a request and a worker, in Definition 2 and 3.

Definition 2 (Request). A request is denoted by $r=\left\langle o_{r}, d_{r}, t_{r}, e_{r}, c_{r}\right\rangle$. This request appears on the platform at time $t_{r} . o_{r} \in V$ is the request's origin, $d_{r} \in V$ is the destination, and $e_{r}$ is the deadline time. The size $c_{r}$ denotes the number of passengers or parcels that need to be carried.

In a real-world platform, a request is said to be served if it is picked up at the origin $o_{r}$ by a worker with enough capacity (compared with $c_{r}$ ) after the appearance time $t_{r}$ and delivered to the destination $d_{r}$ before the deadline time $e_{r}$. A worker is formulated as follows.

Definition 3 (Worker). A worker is denoted by $w=\left\langle c_{w}, \mathcal{S}_{\mathcal{R}}, t_{0}\right\rangle$, where $R$ is the set of requests that have been allocated to this worker but undelivered, $c_{w}$ is the worker's capacity, and $\mathcal{S}_{\mathcal{R}}$ is his current route at the time $t_{0}$. Here, the route is defined as a sequence of vertices in $V$, i.e., $\mathcal{S}_{\mathcal{R}}=\left\langle v_{0}, v_{1}, \cdots, v_{n}\right\rangle$, where $v_{0}$ is his current location, and $v_{1}, \cdots, v_{n}$ is either an origin or a destination of an

Figure 4: Insertion cases of all possible pairs $(i, j)$.
undelivered request in $R$. Besides, we use $\operatorname{arr}\left[v_{k}\right]$ to denote the arrival time at the location $v_{k}$ by following this route, i.e.,

$$
\operatorname{arr}\left[v_{k}\right]= \begin{cases}t_{0}, & k=0 \\ \operatorname{query}\left(v_{k-1}, v_{k}, \operatorname{arr}\left[v_{k-1}\right]\right), & k>0\end{cases}
$$

In Definition 3, the worker's capacity is limited to $c_{w}$. For instance, $c_{w}$ is often $3-4$ in ride-sharing [16, 26, 41], while could be $80-200$ in food/parcel delivery [24, 30, 39, 50]. According to the above definition, we can easily compute the pickup time and delivery time of a request, which are denoted by $p i k\left(o_{r}\right)$ and $\operatorname{del}\left(d_{r}\right)$, respectively. A route is said to be feasible if all the requests assigned to this worker are delivered before the deadline.

### 2.2 Problem Definition

According to the above concepts and conventional definition [35, 39] of the insertion operation, we present the formal definition of the insertion operator for shared mobility on time-dependent road networks ("time-dependent insertion" as short).

Definition 4 (Time-dependent Insertion). Given a worker $w$ and a request $r^{+}$that newly appears at time $t_{r^{+}}$, this operation finds a new route for this worker $S^{*}$ with the minimum increased travel time $o b j^{*}$ in real-time to serve all the requests $R^{+}$(i.e., $\left.R^{+}=R \cup r^{+}\right)$ while satisfying the following constraints:

- Completion Constraint. All the requests must be served.
- Order Constraint. The relative orders of vertices in $S_{R}$ remain the same in $S^{*}$. In other words, the new request's origin and destination are sequentially inserted at some positions of the worker's current route.
- Deadline Constraint. The worker must deliver all the requests to their destinations before their deadlines.
- Capacity Constraint. At any time, the total size of requests that this worker has picked up but not delivered is no larger than the worker's capacity.

The insertion operator $\operatorname{insert}(i, j)$ indicates that the new request's origin/destination is inserted at the $i / j$-th position of the current route $\mathcal{S}_{\mathcal{R}}$ (i.e., before the vertex $v_{i} / v_{j}$ ), where $1 \leq i \leq j \leq n+1$. Fig. 4 shows all four cases of the new route after inserting the new request. The operator preserves the original order of $\mathcal{S}_{\mathcal{R}}$, as practiced in real industry [41, 42], to avoid reducing passenger satisfaction [28].

### 2.3 Baseline Method

An extension of an existing $O\left(n^{3}\right)$-time method for static road networks [39] serves as our baseline for developing an insertion
operator on time-dependent road networks. We present the implementation details of this method in Algo. 1.

Main Idea. The intuition behind the baseline method is as follows. Specifically, we enumerate all pairs of potential positions $(i, j)$ to insert the new request's origin $o_{r^{+}}$and new request's destination $d_{r^{+}}$and obtain a possible route $S_{R^{+}}$(lines 2-4). Based on this possible route, we compute the new arrival time at each vertex and check the feasibility (lines 5). If there is no constraint violation and the increased travel time of $S_{R^{+}}$is shorter than the optimal route before checking insert $(i, j)$, we set $S_{R^{+}}$as $S^{*}$ (lines 6-8).
Complexity Analysis. Suppose the time cost of the shortest arrival time query on a time-dependent road network is $O(q)$. Lines 23 take $O\left(n^{2}\right)$ time. Lines 5-6 take $O(n q)$ time. Thus, the overall time complexity is $O\left(n^{3} q\right)$ time. For brevity, existing work usually ignores the term $O(q)$, so the baseline takes cubic time. We will also follow this convention in the rest of the paper.

```
Algorithm 1: Baseline: Cubic Time Insertion [39]
    Input: a worker \(w\) and a new request \(r^{+}\)
    Output: route \(S^{*}\) with min increased travel time \(o b j^{*}\)
    \(S^{*} \leftarrow S_{R}, o b j^{*} \leftarrow+\infty, \operatorname{arr}\left[v_{0}\right] \leftarrow t_{0} ;\)
    for \(i \leftarrow 1\) to \(n+1\) do
        for \(j \leftarrow i\) to \(n+1\) do
            \(S_{R^{+}} \leftarrow\) insert new request's \(o_{r^{+}} / d_{r^{+}}\)before the
            vertex \(v_{i} / v_{j}\) in \(S_{R}\);
            if \(S_{R^{+}}\)satisfies all constraints in Definition 4 then
                \(o b j \leftarrow\) increased travel time of \(S_{R^{+}}\);
                if \(o b j<o b j^{*}\) then
                        \(S^{*} \leftarrow S_{R^{+}}, o b j^{*} \leftarrow o b j ;\)
    return \(S^{*}, o b j^{*}\);
```

## 3 OUR METHODOLOGY

To address the limitations of the baseline method, we introduce a data summary called the compound travel functions, which accelerates the delay time query along the worker's route. This data structure enables efficient computation of the increased travel time and feasibility checking in $O(1)$ time. This directly reduces the time complexity of a time-dependent insertion to $O\left(n^{2}\right)$ by consuming $O\left(n^{2}\right)$ space cost. After that, we show how to find the optimal $i$ in $O(1)$ time when $j$ is given along a feasible route of the worker by solely utilizing the compound travel function from $v_{j-1}$ to $v_{j}$. As a result, both time and space complexity can be further improved to $O(n)$ by enumerating $j$ along the worker's feasible route.

### 3.1 Preliminary

### 3.1.1 Data Summary Model: Compound Travel Functions.

To accelerate the increased travel time computation and feasibility checking, we calculate one $\operatorname{ComTravel}\left(v_{x}, v_{y}, t\right)$ in Definition 5 for each pair of vertices $\left(v_{x}, v_{y}\right)$ in the feasible route $S_{R}=\left\langle v_{0}, v_{1}, \ldots v_{n}\right\rangle$ where $0<x<y<n$. This function represents the travel time when starting from vertex $v_{x}$ at time $t$ and ending at vertex $v_{y}$.

We refer to the compound travel functions maintained for a worker's current route as the data summary model. The definition of compound travel functions along a route is given as follows.

Definition 5 (Compound Travel Function). Given two vertexes $v_{x}$ and $v_{y}$ associated with the sub-route $\left\langle v_{x}, v_{x+1}, \cdots, v_{y}\right\rangle$ in $S_{R}$, the compound travel function ComTravel $\left(v_{x}, v_{y}, t\right)$ indicates the travel time of the route when starting from $v_{x}$ to $v_{y}$ at time, $\operatorname{ComTravel}\left(v_{x}, v_{y}, t\right)$ $=f_{y-1, y}^{\prime}\left(f_{y-2, y-1}^{\prime}\left(\cdots f_{x, x+1}^{\prime}(t)\right)\right)-t$.

For a successive sub-route $\left\langle v_{k}, v_{k+1}\right\rangle \in S_{R}(0 \leq k \leq n-1)$, $f_{k, k+1}^{\prime}(t)$ is the weight function of it. If we assume that there is a shortest path ( $u_{0}=v_{k}, u_{1}, u_{2}=v_{k+1}$ ) in the road connecting $v_{k}$ and $v_{k+1}$, with $\left(u_{0}, u_{1}\right)$ and $\left(u_{1}, u_{2}\right)$ being edges. We can obtain two weight functions $f_{0,1}(t)$ and $f_{1,2}(t)$ associated with these edges. Starting from $u_{0}$ at time $t_{0}$, we can compound $t_{0}$ to the edge weight function $f_{0,1}(t)$ to obtain the arrival time at $u_{1}$, represented as a function $f_{0,1}\left(t_{0}\right)$. We can then compound $f_{0,1}\left(t_{0}\right)$ into the edge weight function $f_{1,2}(t)$, which gives the function $f_{1,2}\left(f_{0,1}\left(t_{0}\right)\right)$ representing the arrival time at $u_{2}$ when starting from $v_{0}$ at $t_{0}$. Finally, we can use the $f_{k, k+1}^{\prime}\left(t_{0}\right)=f_{1,2}\left(f_{0,1}\left(t_{0}\right)\right)$ to denote the weight function along the sub-route. It can be calculated by the existing shortest path algorithm [37] on time-dependent road networks.
Example 2. As the sub-route $\left\langle o_{1}, o_{2}, d_{2}\right\rangle$ shown in Fig. 1. If the weight functions for $\left\langle o_{1}, o_{2}\right\rangle$ and $\left\langle o_{2}, d_{2}\right\rangle$ are $w_{o_{1}, o_{2}}(t)=\{(0,10),(60,20)\}$ and $w_{o_{2}, d_{2}}(t)=\{(0,5),(60,30)\}$, respectively. At time 0 , the travel cost from $o_{1}$ to $d_{2}$ is calculated as $10+\left(5+10 * \frac{30-5}{60-0}\right)$, where 10 is the cost of $\left\langle o_{1}, o_{2}\right\rangle$ at time 0 , and $\left(5+10 * \frac{30-5}{60-0}\right)$ denotes the cost of $\left\langle o_{2}, d_{2}\right\rangle$ when starting the edge at time 10 . Using this method, we can calculate the compound travel function ComTravel $\left(o_{1}, d_{2}, *\right)$.

### 3.1.2 Query the Delay Time by Compound Travel Function.

The compound travel function accelerates the travel time computation to $O(1)$ time, based on this data structure, we design a novel spatiotemporal query delay time query along the worker's route.

Definition 6 (Delay time query). Given two vertexes $v_{x}$ and $v_{y}$ in worker's route, where $v_{y}$ locates after $v_{x}$, the delay time query delayquery $\left(v_{x}, v_{y}, t\right)$ retrieves the delay time at $v_{y}$ when the arrival time $v_{x}$ is delayed to time $t$, where delayquery $\left(v_{x}, v_{y}, t\right)=\operatorname{arr}\left[v_{x}\right]+$ ComTravel $\left(v_{x}, v_{y}, t\right)-\operatorname{arr}\left[v_{y}\right]$.

After inserting the new origin $o_{r^{+}} /$destination $d_{r^{+}}$before $v_{i} / v_{j}$ in $S_{R}$. The new arrival time at $v_{i}$ and $v_{j}$ are dependent on the pickup time and delivery time of $r^{+}$. For vertices in the sub-route $\left\langle v_{i+1}, v_{i+2}, \ldots, v_{j-1}\right\rangle$, which are located after $v_{i}$ and before $v_{j}$, the delay time at these locations are dependent on the new arrival time at $v_{i}$, which can be calculated by the delay queries delayquery $\left(v_{i}, \cdot, \cdot\right)$. The sub-route $\left\langle v_{j+1}, v_{j+2}, \cdots, v_{n}\right\rangle$ consists of the remaining vertices in $S_{R}$ after $v_{j}$, and the delay time of these vertices are dependent on the arrival time to $v_{j}$, which can be calculated by the delay queries delayquery $\left(v_{j}, \cdot, \cdot\right)$. We next show how to calculate the arrival time of each vertex in $S_{R^{+}}$, based on its original position in $S_{R}$.

- Computing for pickup time: New origin $o_{r^{+}}$is inserted before $v_{i}$ and after $v_{i-1}$, so the pickup time can be calculated from arrival time to $v_{i-1}$ in the original route.

$$
\begin{equation*}
\operatorname{pik}\left(o_{r^{+}}\right)=\operatorname{query}\left(v_{i-1}, o_{r^{+}}, \operatorname{arr}\left[v_{i-1}\right]\right) \tag{2}
\end{equation*}
$$

- Delay time query in $\left\langle v_{i}, v_{i+1}, \cdots, v_{j-1}\right\rangle$ : The insertion of the new origin $o_{r^{+}}$before $v_{i}$ caused the delay at vertices in this sub-route, which needs to be calculated. The new arrival time at $v_{i}$ is dependent on the pickup time, $\operatorname{arr}^{\prime}\left[v_{i}\right]=$
query $\left(o_{r^{+}}, v_{i}, p i k\left(o_{r^{+}}\right)\right)$. For other vertices, the delay time caused by new arrival time $a \mathrm{ar}^{\prime}\left[v_{i}\right]$ can be calculated as $\operatorname{arr}\left[v_{k}\right]+\operatorname{delayquery}\left(v_{i}, v_{k}, \operatorname{arr}{ }^{\prime}\left[v_{i}\right]\right), i<k<j$.
- Computing for delivery time: We consider two cases. If $i<j, d_{r^{+}}$is inserted after $v_{j-1}$ and before $v_{j}$, the delivery time can be calculated from the new arrival time to $v_{j-1}$ (as shown in Figure 4a and 4c). On the other hand, if $i=j$, $d_{r^{+}}$is inserted immediately after $o_{r^{+}}$, so the delivery time can be calculated from the pickup time of the new request (as shown in Figure 4b and 4d).

$$
\operatorname{del}\left(d_{r^{+}}\right)= \begin{cases}q \operatorname{uer} y\left(v_{j-1}, d_{r^{+}}, \operatorname{arr} r^{\prime}\left[v_{j-1}\right]\right), & i<j  \tag{3}\\ q \operatorname{uery}\left(o_{r^{+}}, d_{r^{+}}, \operatorname{pik}\left(o_{r^{+}}\right)\right), & i=j\end{cases}
$$

- Delay time query in $\left\langle v_{j}, v_{j+1}, \cdots, v_{n}\right\rangle$. After inserting $d_{r^{+}}$, the new arrival time at $v_{j}$ is dependent on the delivery time, $\operatorname{arr}^{\prime}\left[v_{j}\right]=q u e r y\left(d_{r^{+}}, v_{j}, \operatorname{del}\left(d_{r^{+}}\right)\right)$. For other vertices, the delay time caused by the new arrival time at $v_{j}$ can be calculated as $\operatorname{arr}\left[v_{k}\right]+\operatorname{delayquery}\left(v_{j}, v_{k}, \operatorname{arr} r^{\prime}\left[v_{j}\right]\right), j<$ $k \leq n$
Based on the delay time query in Definition 6, the time complexity of the calculations for each possible pair $(i, j)$ is $O(1)$.

### 3.2 Improve Time Complexity to $O\left(n^{2}\right)$ by using $O\left(n^{2}\right)$ Compound Travel Functions

Basic Idea. To accelerate the constraints checking and increased travel time computation from $O(n)$ to $O(1)$ in the baseline, a compound travel function is built for each insertion position pair $(i, j)$. Therefore, a total of $O\left(n^{2}\right)$ compound travel functions are maintained. These functions compute the delay time in each vertex after insertion in $O(1)$ time, enabling efficient constraint checking and calculation of the increased travel time.

### 3.2.1 Checking Constraints by using $O\left(n^{2}\right)$ Compound Travel Functions.

Given a possible $(i, j)$ pair for insertion, the feasibility of the new route must be verified against two constraints: the deadline constraint and the capacity constraint.
Checking Deadline Constraint. As discussed in Sec. 3.1.2, we first use Eq. (4) to calculate the arrival time of each vertex in $S_{R^{+}}$ in $O(1)$ time. For vertexes $v_{i}$ and $v_{j}$, the new arrival times are dependent on the pickup time and delivery time of the new request, two query () functions are invoked to calculate the new arrival time to them respectively. For vertexes locate between $v_{i+1}$ and $v_{j-1}$, delayquery $\left(v_{i}, *, *\right)$ query the delay time at these vertices. Similarly, the delay time queries delayquery $\left(v_{j}, *, *\right)$ can be utilized to calculate the delay times of vertexes located after $v_{j}$. The time complexity of the shortest arrival time query and the delay time query based on compound travel functions are both $O(1)$. Therefore, for each possible insertion position pair ( $i, j$ ), we can calculate the arrival time of each vertex belonging to $S_{R^{+}}$in $O(1)$ time.

$$
\operatorname{arr}^{\prime}\left[v_{k}\right]= \begin{cases}\operatorname{arr}\left[v_{k}\right], & k<i  \tag{4}\\ \operatorname{query}\left(o_{r^{+}}, v_{i}, \operatorname{pik}\left(o_{r^{\prime}}\right)\right), & k=i \\ \operatorname{arr}\left[v_{k}\right]+\operatorname{delayquery}\left(v_{i}, v_{k}, \operatorname{arr} r^{\prime}\left[v_{i}\right]\right), & i<k<j \\ \operatorname{query}\left(d_{r^{+}}, v_{j}, \operatorname{del}\left(d_{r^{\prime}}\right)\right), & k=j \\ \operatorname{arr}\left[v_{k}\right]+\operatorname{delayquery}\left(v_{j}, v_{k}, \operatorname{arr}^{\prime}\left[v_{j}\right]\right), & j<k \leq n\end{cases}
$$

Figure 5: Checking deadline constraint.
We further use latest $\left[v_{k}\right]$ to denote the latest arrival time at vertex $v_{k}$ without violating any deadline constraints at $v_{k}$ and all vertices after $v_{k}$. Similar to calculating the arrival time at a vertex, latest $\left[v_{k}\right]$ can be computed from the compound travel function.

To ensure that the worker satisfies the deadline constraint for all vertices from $v_{k}$ to $v_{n}$, we need to calculate latest $\left[v_{k}\right]$ in reverse order for each successive sub-route $\left\langle v_{k}, v_{k+1}\right\rangle \in S_{R}$, where $k$ ranges from $n$ to 0 . The latest arrival time for each vertex can be calculated using the following equation, where latest $\left[v_{n}\right]$ is the deadline time of the request whose destination is the last vertex $v_{n}$ :

$$
\left\{\begin{array}{l}
\text { latest }\left[v_{k}\right]+\operatorname{ComTravel}\left(v_{k}, v_{k+1}, \text { latest }\left[v_{k}\right]\right)=\operatorname{latest}\left[v_{k+1}\right],  \tag{5}\\
\text { latest }\left[v_{n}\right]=e_{r}, \text { when } v_{n}=d_{r}
\end{array}\right.
$$

The following lemmas check the deadline constraint.
Lemma 1. The deadline constraint will not be violated if and only if (1) pik $\left(o_{r^{+}}\right) \leq e_{r^{+}}$; (2) arr ${ }^{\prime}\left[v_{i}\right]=q u e r y ~\left(o_{r^{+}}, v_{i}, p i k\left(o_{r^{+}}\right)\right) \leq$ latest $\left[v_{i}\right] ;(3) \operatorname{del}\left(d_{r^{+}}\right) \leq e_{r^{+}} ;(4) \operatorname{arr}^{\prime}\left[v_{j}\right]=q u e r y\left(d_{r^{+}}, v_{j}, \operatorname{del}\left(d_{r^{+}}\right)\right)$ $\leq$ latest $\left[v_{j}\right]$;

Proof. We prove this lemma by considering the general insertion case, as depicted in Fig. 5. Given a new request $r^{+}$, we first calculate the pickup and delivery time in conditions (1) and (3), respectively. These two conditions ensure that the new potential route will not violate the deadline constraint of $r^{+}$. Condition (2) calculates the new arrival time at $v_{i}$ after picking up $r^{+}$, denoted as $a r r^{\prime}\left[v_{i}\right]$. To ensure that the deadline constraints after $v_{i}$ are satisfied, $a r r^{\prime}\left[v_{i}\right]$ cannot exceed the latest arrival time to $v_{i}$, which is denoted as latest $\left[v_{i}\right]$. Similarly, for vertex $v_{j}$, condition (4) calculates the new arrival time after serving the new request, denoted as $\mathrm{arr}^{\prime}\left[v_{j}\right]$. In order not to violate the deadline constraints for vertices located after $v_{j}$, condition (4) guarantees that $\operatorname{arr}^{\prime}\left[v_{j}\right]$ is earlier than the latest arrival time to $v_{j}$, which is denoted as latest $\left[v_{j}\right]$.

Checking Capacity Constraint. To check the capacity constraint in $O(1)$ time, we use $n u m\left[v_{k}\right]$ to represent the number of requests picked up but not yet delivered at vertex $v_{k}$, following previous work [35]. We calculate this array according to the following rules, where $v_{k}$ is either a pickup location $o_{r}$ or a delivery location $d_{r}$ for a request $r \in R$ :

$$
\operatorname{num}\left[v_{k}\right]= \begin{cases}\operatorname{num}\left[v_{k-1}\right]+c_{r}, & v_{k}=o_{r}  \tag{6}\\ \operatorname{num}\left[v_{k-1}\right]-c_{r}, & v_{k}=d_{r}\end{cases}
$$

Lemma 2. [35] Along the new route, the capacity constraint will not be violated if and only if (1) num $\left[v_{i-1}\right] \leq c_{w}-c_{r^{+}}$; (2) $\operatorname{num}\left[v_{k}\right] \leq c_{w}-c_{r^{+}}, i<k \leq j$.

Please refer to Ref. [35] for the proof of Lemma 2.

### 3.2.2 Computation of Increased Travel Time.

If the position pair $(i, j)$ satisfies both deadline and capacity constraints, we can call this pair feasible for insertion. Then the increased travel time can be calculated as obj in the following:

$$
o b j= \begin{cases}\operatorname{delayquery}\left(v_{j}, v_{n}, \operatorname{arr^{\prime }}\left[v_{j}\right]\right), & j \leq n  \tag{7}\\ \operatorname{del}\left(d_{r^{+}}\right)-\operatorname{arr}\left[v_{n}\right], & \text { otherwise }\end{cases}
$$

When $j \leq n$, the new request is delivered before reaching $v_{j}$, resulting in a delay at $v_{j}$. By utilizing the compound travel functions maintained for $v_{j}$, we can directly perform the delay time query to the last vertex $v_{n}$ to calculate the increased travel time caused by the delay at $v_{j}$ in $O(1)$ time. On the other hand, if the new request is the last one to be delivered, as shown in Figure 4c and 4d, the increased travel time is simply the delivery time of the new request minus the arrival time of the last location in the original route.

```
Algorithm 2: Quadratic Time Insertion
    Input: a worker \(w\) with a feasible route \(S_{R}\) and a request \(r^{+}\)
    Output: new route \(S^{*}\) for \(w\) and the minimum increased
            travel time obj*
    \(S^{*} \leftarrow S_{R}, o b j^{*} \leftarrow+\infty\);
    Initialize latest, num by Eq. (5)-Eq. (6) ;
    Compound travel functions
    ComTravel( \(i, j, \cdot), \forall i, j, 0<i<j<n\) by Definition 5 ;
    for \(i \leftarrow 1\) to \(n+1\) do
        if Lemma 1(1) or (2) violated then continue;
        if Lemma 2 (1) violated then continue;
        for \(j \leftarrow i\) to \(n+1\) do
            if Lemma 1 (3) or (4) violated then continue;
            if Lemma 2 (2) violated then break;
            \(o b j \leftarrow E q\). (7) ;
            if \(o b j<o b j^{*}\) then
                \(o b j^{*} \leftarrow o b j, i^{*} \leftarrow i, j^{*} \leftarrow j ;\)
    if \(o b j^{*}<+\infty\) then
        \(S^{*} \leftarrow\) insert \(o_{r}\) at \(i^{*}\)-th and \(d_{r}\) at \(j^{*}\)-th in \(S_{R}\);
        Get new arrival time of \(S^{*}\) by \(E q\). (4) ;
    return \(S^{*}, o b j^{*}\);
```

3.2.3 Algorithm Details.

Main Idea. We enumerate all possible ( $i, j$ ) pairs for insertion in the algorithm, and build one compound travel function for each pair. With the total of $O\left(n^{2}\right)$ functions, the constraints checking and increased time computation can be achieved in $O(1)$ time. The new arrival times and increased travel time are updated by Eq. (4) and Eq. (7) in $O(1)$ time respectively. The deadline constraint is checked for $v_{i}$ using Lemma 1 (1)-(2) after inserting $o_{r^{+}}$, and the capacity constraint is checked using Lemma 2 (1). For $v_{j}$, the algorithm uses Lemma 1 (3)-(4) and Lemma 2 (2) to check the deadline and capacity constraints after inserting $d_{r^{+}}$before it. All these feasibility checks have a time cost of $O(1)$.
Complexity Analysis. Algo. 2 shows the details. Line 2 initializes auxiliary arrays latest, num. Line 3 computes the compound travel function between any two vertexes along $S_{R}$ to build the data summary model. Lines 4-9 enumerate possible positions to insert $o_{r^{+}}$and $d_{r^{+}}$, checking the deadline and capacity constraints in

Table 2: ComTravel of $S_{R}$ in Algo. 2

|  | $o_{1}$ | $o_{2}$ | $d_{2}$ | $d_{1}$ |
| :---: | :---: | :---: | :---: | :---: |
| $o_{1}$ | $\times$ | ComTravel $\left(o_{1}, o_{2}, t\right)$ | ComTravel $\left(o_{1}, d_{2}, t\right)$ | $\operatorname{ComTravel}\left(o_{1}, d_{1}, t\right)$ |
| $o_{2}$ | $\times$ | $\times$ | ComTravel $\left(o_{2}, d_{2}, t\right)$ | $\operatorname{ComTravel}\left(o_{2}, d_{1}, t\right)$ |
| $d_{2}$ | $\times$ | $\times$ | $\times$ | ComTravel $\left(d_{2}, d_{1}, t\right)$ |
| $d_{1}$ | $\times$ | $\times$ | $\times$ | $\times$ |

Figure 6: Update arrival time with ComTravel.
$O(1)$ time for each position. If $(i, j)$ is feasible, the increased travel time is calculated in line 10 in $O(1)$ time. Therefore, the total time complexity of Algo. 2 is $O\left(n^{2}\right)$, and the space complexity is also $O\left(n^{2}\right)$, as the worker maintains $O\left(n^{2}\right)$ compound travel functions.
Example 3. Back to the settings in Fig. 1. For the current feasible route $S_{R}=\left\langle o_{1}, o_{2}, d_{2}, d_{1}\right\rangle$, the compound travel functions along $S_{R}$ are shown in Table 2. The algorithm computes $(3+2+1)$ compound travel functions. For each vertex in $S_{R}$, the algorithm computes and maintains compound travel functions to all vertices after it. To serve $r_{3}$, we consider the first possible insertion pair (1,1). As shown in Figure 6, by inserting $o_{3}$ and $d_{3}$ before $o_{2}$, the resulting increase in travel time can be directly calculated as delayquery $\left(o_{2}, d_{1}, \operatorname{arr}^{\prime}\left[o_{2}\right]\right)$ in $O(1)$ time. This delay time query is facilitated by the compound travel function ComTravel ( $o_{2}, d_{1}$, arr $\left.^{\prime}\left[o_{2}\right]\right)$, which is maintained by $o_{2}$. Alternatively, without this function, the sequential invocation of the shortest arrival time query query $\left(d_{2}, d_{1}\right.$, query $\left.\left(o_{2}, d_{2}, \operatorname{arr}{ }^{\prime}\left[o_{2}\right]\right)\right)$ ) scans the sub-route $<o_{2}, d_{2}, d_{1}>$ to calculate the increased travel time.
Correctness. The algorithm can find the optimal position pair $(i, j)$ with the minimum increased travel time to deliver the assigned new request $r^{+}$. The order constraint can be trivially verified by the pseudo code of Algo. 2. The feasibility of $(i, j)$ for insertion is ensured by the correctness of Lemma 1 and Lemma 2, while Eq. (4) - Eq. (7) guarantee the minimum increased travel time.

Discussion. This algorithm requires $O\left(n^{2}\right)$ compound travel functions, which results in significant memory overhead. Based on our observation (detail in Sec. 3.3), we find that these functions contain redundancies. Therefore, we try to further optimize the number of compound travel functions to improve the time complexity of the insertion.

### 3.3 Optimize Time Complexity to $O(n)$ by using Only $O(n)$ Compound Travel Functions

Observation: Two compound travel functions for each vertex $v_{j}$ is sufficient. As Fig. 7 shows, we use opt $t_{i}\left[d_{2}\right]$ records the optimal $i$ when $j=2$, i.e., find the optimal position to insert $o_{r^{+}}$ when inserting $d_{r^{+}}$before $d_{2}$. Based on the order constraint, there are only two cases for $i$ value: (1) Fig. 7a, when $\mathrm{opt}_{i}\left[d_{2}\right]=o p t_{i}\left[o_{2}\right]$, the optimal $i$ value is same as when insertion the $d_{r^{+}}$before the previous vertex $o_{2}$; (2) Fig. 7b, when opt ${ }_{i}\left[d_{2}\right] \neq o p t_{i}\left[o_{2}\right]$, the optimal $i$ is updated. Based on the FIFO property, the determining factor is which case causes more time delay at $d_{2}$, as more time delay at $d_{2}$ results in more time delay at the last vertex $v_{n}$. To determine
the optimal $i$ value recorded in $o p t_{i}\left[d_{2}\right]$, the delay time at $d_{2}$ can be calculated using one compound travel function from $o_{2}$ to $d_{2}$ in Fig. 7a, or using Eq. (4) in Fig. 7b. Then the increased travel time of the route can be queried by another compound travel function from $d_{2}$ to the last vertex $d_{1}$. Therefore, for $d_{2}$, two compound travel functions are sufficient to find the optimal insertion position pair (opt $\left.t_{i}\left[d_{2}\right], 2\right)$ before it.

Figure 7: When $j=2$, two cases for optimal $i$ value
Basic Idea. The optimal insertion position $i$ can be searched in $O(1)$ time by enumerating the possible values of $j$. This is achieved by performing a delay time query from $v_{j-1}$ to $v_{j}$. The increased travel time caused by delivering the new request before $v_{j}$ then can be calculated by performing a delay time query from $v_{j}$ to the last vertex $v_{n}$. Thus the worker only needs to maintain at most two compound travel functions for each vertex $v_{j}$ in the route. As a result of the optimization, both the time and space costs are reduced from $O\left(n^{2}\right)$ to $O(n)$.

### 3.3.1 Computing optimal in $O$ (1) Time When Sequentially Increase $j$.

We try to only enumerate the positions $j$ to insert the destination of the new request while finding the optimal $i$, instead of enumerating all possible $(i, j)$ pairs. If destination $d_{r^{+}}$is inserted before $v_{j}$ in route $S_{R}$, then the origin $o_{r^{+}}$must also be inserted before $v_{j}$.
Calculate $o p t_{i}\left[v_{j}\right]$ as $i$ by One Compound Travel Function Between $v_{j-1}$ and $v_{j}$. We use $o p t_{i}\left[v_{j}\right]$ to record the optimal value of $i$ when enumerating the $j$ position along $S_{R}$. Specifically, by inserting $o_{r^{+}}$at $o p t_{i}\left[v_{j}\right]$, we can achieve the shortest arrival time at vertex $v_{j}$, resulting in a better route with a shorter increased travel time due to the first-in-first-out (FIFO) property. Additionally, we use $\operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j}\right]$ to denote the arrival time at vertex $v_{j}$ if we insert $o_{r^{+}}$ at the position calculated before in $o p t_{i}\left[v_{j-1}\right] \in\{i: 0<i<j\}$, it can be calculated by delayquery $\left(v_{j-1}, v_{j}, *\right)$. If the new potential $j$ th position does not satisfy either the deadline constraint or capacity constraint for inserting $o_{r^{+}}$, then we set $o p t_{i}\left[v_{j}\right]=$ NIL. Otherwise, we can calculate the value based on the following lemma:
Lemma 3. Given a potential vertex $v_{j}$ for inserting $d_{r^{+}}$before it, we update $o p t_{i}\left[v_{j}\right]=j$ if and only if (1) num $\left[v_{j-1}\right] \leq c_{w}-c_{r^{+}}$; (2) pik( $\left.o_{r^{+}}\right) \leq e_{r^{+}}$and query $\left(o_{r^{+}}, v_{j}, p i k\left(o_{r^{+}}\right)\right) \leq$latest $\left[v_{j}\right]$; (3) query $\left(o_{r^{+}}, v_{j}, \operatorname{pik}\left(o_{r^{+}}\right)\right)<\operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j}\right]$. Here, $\operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j}\right]$ can be calculated using the delay time query from $v_{j-1}$ to $v_{j}$ as $a r r_{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]+$ delayquery $\left(v_{j-1}, v_{j}\right.$, arr $\left._{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]\right)$.

Proof. Condition (1) checks the capacity constraint and ensures that there is enough capacity for the worker to pick up $r^{+}$
at $v_{j}$. Condition (2) ensures that the deadline constraints are satisfied if $o_{r^{+}}$is inserted before $v_{j}$. Condition (3) guarantees that inserting $o_{r^{+}}$at the new potential $j$-th position results in a shorter travel time compared to inserting it in positions $\{i: 0<i<j\}$. This can be proven by contradiction. Let us assume that the optimal position for inserting the new request's origin $o_{r^{+}}$is recorded in $o p t_{i}\left[v_{j-1}\right]$ and lies within the set $\{i: 0<i<j\}$. We insert $o_{r^{+}}$at $o p t_{i}\left[v_{j-1}\right]$, the arrival time at $v_{j}$ can be calculated by delay time query from $v_{j-1}$ to $v_{j}$. Specifically, it can be expressed as $\operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j}\right]=\operatorname{arr} r_{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]+\operatorname{delayquery}\left(v_{j-1}, v_{j}, \operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]\right)$. However, if condition (3) is satisfied, inserting $o_{r^{+}}$at the new potential position $j$ results in an earlier arrival time at $v_{j}$. If $o p t_{i}\left[v_{j-1}\right]$ is the best position to insert $o_{r^{+}}$, we would obtain a route with a shorter travel time compared to inserting $o_{r^{+}}$before $v_{j}$. However, according to the FIFO property, if we choose $o p t_{i}\left[v_{j-1}\right]$, the route would arrive later at $v_{j}$ and the final vertex $v_{n}$ with a larger delay, which contradicts the assumption. Therefore, $j$ is a better position to insert $o_{r^{+}}$, and we update $o p t_{i}\left[v_{j}\right]=j$.

### 3.3.2 Checking Constraints in $O(1)$ by using Only $O(n)$ Compound Travel Functions.

We also need to check both capacity and deadline constraints. The capacity constraint check is similar to Lemma 2. After computing the optimal $i$ value in $o p t_{i}\left[v_{j}\right]$, we first update the new arrival time at $v_{j}$, then check the deadline constraint for inserting the new destination at position $j$.
Update New Arrival Time At $v_{j}$ by One Compound Travel Function between $v_{j-1}$ to $v_{j}$. We first update the arrival time at $v_{j}$ based on $o p t_{i}\left[v_{j}\right]$ for further feasibility checking. If $o p t_{i}\left[v_{j}\right]=j$, we need to invoke the shortest arrival time query query() to calculate the new arrival time at $v_{j}$. Otherwise, if $o p t_{i}\left[v_{j}\right]=o p t_{i}\left[v_{j-1}\right]$, it indicates the the optimal position to insert $o_{r^{+}}$is one of the positions in $\{i: 0<i<j\}$. To update the arrival time at $v_{j}$, we can rely on the delay time query from $v_{j-1}$ to $v_{j}$.

The new arrival time at $v_{j}$ is updated based on the following rules in $O(1)$ time. If $o p t_{i}\left[v_{j}\right]=j, o_{r^{+}}$is also inserted at $j$-th position. Otherwise, opt $t_{i}\left[v_{j}\right]=o p t_{i}\left[v_{j-1}\right], o_{r^{+}}$is inserted at one position in $\{i: 0<i<j\}$ :

$$
\begin{align*}
& \operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j}\right]= \\
& \begin{cases}\text { query }\left(o_{r^{+}}, v_{j}, \operatorname{pik}\left(o_{r^{+}}\right)\right), & o p t_{i}\left[v_{j}\right]=j \\
\operatorname{arr}_{o_{r^{+}}}\left[v_{j}\right]+\operatorname{delayquery}\left(v_{j-1}, v_{j}, \operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]\right), & \text { otherwise }\end{cases} \tag{8}
\end{align*}
$$

Checking Constraints for $v_{j}$. As for the new destination $d_{r^{+}}$, before considering its insertion into the route at the $j$-th position, we must first verify its feasibility. This verification requires taking into account the worker's capacity constraint, the time constraint of the new request, and the new arrival time at $v_{j}$.

We first calculate the delivery time based on the updated arrival time at $v_{j-1}$ after picking up the new request at position $o p t_{i}\left[v_{j-1}\right]$. The delivery time is calculated as:

$$
\begin{equation*}
\operatorname{del}\left(d_{r^{+}}\right)=\operatorname{query}\left(v_{j-1}, d_{r^{+}}, \operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]\right) \tag{9}
\end{equation*}
$$

Then, we update the arrival time at $v_{j}$ after delivering the new request, by using the delivery time of the new request:

$$
\begin{equation*}
\operatorname{arr}^{\prime}\left[v_{j}\right]=\operatorname{query}\left(d_{r^{+}}, v_{j}, \operatorname{del}\left(d_{r^{+}}\right)\right) \tag{10}
\end{equation*}
$$

Table 3: ComTravel of $S_{R}$ in Algo. 3

|  | 1 | 2 |
| :---: | :---: | :---: |
| $o_{1}$ | ComTravel $\left(o_{1}, o_{2}, t\right)$ | ComTravel $\left(o_{1}, d_{1}, t\right)$ |
| $o_{2}$ | ComTravel $\left(o_{2}, d_{2}, t\right)$ | ComTravel $\left(o_{2}, d_{1}, t\right)$ |
| $d_{2}$ | ComTravel $\left(d_{2}, d_{1}, t\right)$ | $\times$ |
| $d_{1}$ | $\times$ | $\times$ |

Then we can perform the constraints verification by utilizing the following lemma:
Lemma 4. The $j$-th position is a feasible position for inserting $d_{r^{+}}$if and only if (1) $\operatorname{del}\left(d_{r^{+}}\right)=q u e r y\left(v_{j-1}, d_{r^{+}}, \operatorname{arr}_{o_{r^{+}}}^{\prime}\left[v_{j-1}\right]\right) \leq e_{r^{+}} ;$(2) $\operatorname{arr}^{\prime}\left[v_{j}\right]=q u e r y\left(d_{r^{+}}, v_{j}, \operatorname{del}\left(d_{r^{+}}\right)\right) \leq \operatorname{latest}\left[v_{j}\right] ;$ (3) num $\left[v_{j-1}\right] \leq$ $c_{w}-c_{r^{+}}$

Proof. Condition (1) guarantees that inserting the new request's destination at the $j$-th position will not violate its deadline constraint. Following the insertion of $d_{r^{+}}$at the $j$-th position, condition (2) ensures that the new arrival time at $v_{j}$ does not violate any deadline constraints for assigned requests delivered after $v_{j}$. Condition (3) checks the capacity constraint, ensuring that the worker's capacity is not exceeded.

If Lemma 4 confirms that $j$ is a feasible position to insert $d_{r^{+}}$, we follow Eq. (7) to calculate the increased travel time for the insertion position pair ( $o p t_{i}\left[v_{j}\right], j$ ). The delay at the last vertex $v_{n}$ is calculated by the delay time query which is supported by the compound travel function from $v_{j}$ to the last vertex $v_{n}$. Therefore, we can calculate the increased travel time in $O(1)$ time.

```
Algorithm 3: Linear Time Insertion
    Input: a worker \(w\) with a feasible route \(S_{R}\) and a request \(r^{+}\)
    Output: new route \(S^{*}\) for \(w\) and the minimum increased
            travel time obj*

    return \(S^{*}, o b j^{*}\);
```

Figure 8: Enumerating $j$ from 2 to 3

### 3.3.3 Linear Time Algorithm.

Main Idea. We enumerate each potential $j$-th position in the worker's current route $S_{R}$. In each iteration, we use Lemma 3 to determine in $O(1)$ time whether inserting the new origin $o_{r^{+}}$at $j$ is a better choice than other positions before $v_{j}$. The optimal position to insert $o_{r^{+}}$is then computed at $o p t_{i}\left[v_{j}\right]$. Next, we check the feasibility of inserting the new destination $d_{r^{+}}$at position $j$ based on Lemma 4 in $O(1)$ time. If it is feasible, we generate a new route by inserting $o_{r^{+}}$at $o p t_{i}\left[v_{j}\right]$ and $d_{r^{+}}$at position $j$. The new arrival time at $v_{j}$ after delivering the new request is calculated using Eq. (10) in $O(1)$ time. The increased travel time is calculated based on Eq. (7) in $O(1)$ time. All these calculations and feasibility checks have a time cost of $O(1)$.

Complexity Analysis. Line 3 of Algo. 3 computes the compound travel functions of route $S_{R}$. Line 4 takes $O(n)$ time to enumerate the potential position to insert $d_{r^{+}}$. We then check the constraints for inserting $o_{r^{+}}$at the new potential $j$-th position in line 5. If constraints are violated, the optimal position to insert $o_{r^{+}}$lies among the positions $\{i: 0<i<j\}$. Otherwise, the $j$ will be the best position in line 6 . After $o_{r^{+}}$is inserted at $o p t_{i}\left[v_{j}\right]$, the new arrival time at $v_{j}$ is calculated in line 7. The feasibility of inserting $d_{r^{+}}$at $j$ is checked, and the new arrival time at $v_{j}$ is calculated in lines 8-10, each line takes $O(1)$ time. After inserting $o_{r^{+}}$at $o p t_{i}\left[v_{j}\right]$ and $d_{r^{+}}$at $j$, the increased travel time of the newly generated route is calculated from lines 11-13. Therefore, the total time cost of Algo. 3 is $O(n)$. For the space cost, a worker maintains $O(n)$ compound travel functions, because each vertex $v_{j}$ in the route requires at most 2 compound travel functions to be maintained.
Example 4. Back to the settings in Fig. 1. For the current feasible route $S_{R}=\left\langle o_{1}, o_{2}, d_{2}, d_{1}\right\rangle$, the compound travel functions along $S_{R}$ are shown in Table 3. The algorithm computes $(2+2+1)$ compound travel
functions. For each vertex in $S_{R}$, at most two compound travel functions are maintained: one for the previous vertex and the other for the last vertex in the route. For the sake of presentation, we assume that insertion $(1,3)$ is the optimal location pair to serve $r_{3}$. When $j=1$, we determine that $r_{3}$ can only be picked up and delivered before $o_{2}$ thus $o p t_{i}\left[o_{2}\right]=j=1$. The detailed procedure of enumerating $j$ from 2 to 3 is shown in Fig. 8. When $j=2$, as shown in Fig. 8a-Fig. 8b, we first determine if inserting $o_{3}$ before $d_{2}$ (opt $t_{i}\left[d_{2}\right]=2$, marked in yellow) is a better choice than inserting oos before $o_{2}\left(o p t_{i}\left[d_{2}\right]=o p t_{i}\left[o_{2}\right]\right)$, which is shown in Fig. 8a. To compare the new arrival times at vertex $d_{2}$, we consider two cases. If we insert o $o_{3}$ at position 1 , the new arrival time is computed using the delay time query from $o_{2}$ to its next vertex $d_{2}: \operatorname{arr}_{O_{3}}^{\prime}\left[d_{2}\right]+$ delayquery $\left(o_{2}, d_{2}, \operatorname{arr}_{O_{3}}^{\prime}\left[o_{2}\right]\right)$. Here, $\operatorname{arr}_{o_{3}}^{\prime}\left[o_{2}\right]$ is the arrival time at $o_{2}$ if $o_{3}$ is inserted before it. Alternatively, if we insert $o_{3}$ at position 2, the new arrival time at $d_{2}$ can be computed as query $\left(o_{3}, d_{2}, p i k\left(o_{3}\right)\right)$. Following the assumption, by comparing the two arrival times, we obtain query $\left(o_{3}, d_{2}, p i k\left(o_{3}\right)\right)>\operatorname{arr}_{o_{3}}^{\prime}\left[d_{2}\right]+$ delayquery $\left(o_{2}, d_{2}\right.$, arr $\left._{o_{3}}^{\prime}\left[o_{2}\right]\right)$. Therefore, we conclude that inserting $o_{3}$ at position 1 is optimal for all positions before $d_{2}$, thus we have $o p t_{i}\left[d_{2}\right]=o p t_{i}\left[o_{2}\right]=1$. Next, as shown in Fig. 8b, we calculate the increased travel time caused by insertion pair (opt $\mathrm{t}_{i}\left[d_{2}\right]=1, j=2$ ) for $j=2$. The computation is performed using the delay time query from $d_{2}$ to the last vertex $d_{1}: \operatorname{arr}\left[d_{1}\right]+$ delayquery $\left(d_{2}, d_{1}, \operatorname{arr} r^{\prime}\left[d_{2}\right]\right)$, where arr ${ }^{\prime}\left[d_{2}\right]$ is the arrival time at $d_{2}$ after delivering the new request before it. When $j=3$, as shown in Fig. 8c-Fig. 8d, we first evaluate opt $t_{i}\left[d_{1}\right]$ for inserting $o_{3}$ following a similar procedure as before. In the evaluation, we use the delay time query delayquery $\left(d_{2}, d_{1}, \operatorname{arr}_{O_{3}}^{\prime}\left[d_{2}\right]\right)$, where arr ${ }_{o_{3}}^{\prime}\left[d_{2}\right]$ is the arrival time at $d_{2}$ if $o_{3}$ is inserted at opt ${ }_{i}\left[d_{2}\right]$. We then obtain the increased travel time caused by insertion pair $\left(o p t_{i}\left[d_{1}\right]=1, j=3\right)$, and compare it with the value of pair $\left(o p t_{i}\left[d_{2}\right]=\right.$ $1, j=2$ ) in Fig. 8b. The result shows that this is the best insertion pair to serve the new request $r_{3}$.
Correctness. The algorithm can find the optimal position pair (opt $t_{i}\left[v_{j}\right], j$ ) with the minimum increased travel time to deliver the assigned new request $r^{+}$. The order constraint can be verified by Lemma 3. The feasibility of $\left(o p t_{i}\left[v_{j}\right], j\right)$ for insertion is ensured by the correctness of Lemma 3 and Lemma 4, while Eq. (4) - Eq. (7) guarantee the minimum increased travel time.

## 4 EXPERIMENT STUDY

In this section, we first present the experimental setup for our study, then we demonstrate our experimental results.

### 4.1 Experimental Setup

Datasets. The proposed methods are evaluated on three datasets from different applications, with road networks downloaded from OpenStreetMap [5]. The number of edges varies from 80,000 to over 900,000 , with a time domain of 86,400 seconds (a whole day). Timedependent weight functions have $518,282,138,083$, and $1,411,569$ interpolation points, respectively. The TDSP query provided by TD-G-tree [37] is used as the shortest arrival time query query (). Statistical characteristics of the datasets are presented in Table 4.

The first application considered is Ridesharing, using two public datasets from Chengdu and Haikou City, China denoted as Chengdu and Haikou, respectively. The dataset consists of more than 200 k requests during daytime hours (i.e., 8:00 am to 18:00 pm), with origins and destinations mapped to the nearest vertex of the

Table 4: Statistics of datasets.

| Dataset |  | \#(Vertices) | \#(Edges) | \#(Interpolation) |
| :---: | :---: | :---: | :---: | :---: |
| Ridesharing | Chengdu | 423,434 | 913,718 | $1,411,569$ |
|  | Haikou | 41,542 | 89,206 | 138,083 |
| Logistics | Cainiao | 9,936 | 23,872 | 518,282 |

Table 5: Parameter settings.

| Parameters | Settings |
| :---: | :---: |
| Capacity $c_{w}$ | Ridesharing: 3, 5, 10, 15, 20 |
|  | Logistics: $80,100,120,140,160$ |
| Requests release time duration | Ridesharing: |
|  | 2h, 4h, 6h, 8h, 10 h |
|  | Logistics: 4h, 6h, 8h, 10h, 12h |
| Time period: $e_{r}-t_{r}$ (minute) | Ridesharing: 10, 15, 20, 25, 30 |
|  | Logistics: original ddl information |
| Scalability: \# of workers | Ridesharing : 100, 200, 300, 400, 500 |
|  | Logistics: $2 \mathrm{k}, 4 \mathrm{4k}, 6 \mathrm{k}, 8 \mathrm{k}, 10 \mathrm{k}$ |

Table 6: Proposed Algorithms.

| Algorithms | Time Complexity | Space Complexity |
| :---: | :---: | :---: |
| Cubic Time Algorithm | $O\left(n^{3}\right)$ | $O(n)$ |
| Quadratic Time Algorithm | $O\left(n^{2}\right)$ | $O\left(n^{2}\right)$ |
| Linear Time Algorithm | $O(n)$ | $O(n)$ |

road network. The time period from each request release time to the deadline denoted as $e_{r}-t_{r}$, ranges from 10 to 30 minutes while the worker's capacity varies from 3 to 20 , consistent with existing works $[34,39]$ in ridesharing service. Requests released at different timestamps of the day are used to test the methods with varying numbers of requests, ranging from 2 to 10 hours (i.e., 8:00 am-10:00 $\mathrm{am}(2 \mathrm{~h}), 8: 00 \mathrm{am}-12: 00 \mathrm{pm}(4 \mathrm{~h}), \cdots$ 8:00 am to 18:00 pm (10h)).

The second application is Logistics, using a dataset collected in Shanghai by the Cainiao logistics platform [1]. The dataset contains parcel origins, destinations, and deadlines, and is preprocessed by downloading the road network map of Shanghai City. The original deadlines provided in the dataset are utilized, with parameter settings summarized in Table 5.
Compared Algorithms. We compare the following algorithms in this section. Table 6 summaries the algorithms we have proposed.

- Cubic Time Algorithm (Algo. 1 of this paper) [39]. The baseline method implements the insertion operator over timedependent road networks.
- kinetic [18]. A kinetic tree maintains all possible routes to serve the request.
- GreedyDP [35]. A dynamic programming based algorithm to plan routes of requests.
- Quadratic Time Algorithm (Algo. 2 of this paper). It generates new potential routes by enumerating all possible $(i, j)$ pairs.
- Linear Time Algorithm (Algo. 3 of this paper). It enumerates $j$ and find the optimal $i$ in $O(1)$ time.
Metrics. To evaluate time-dependent insertion performance, we vary the following values (1) worker's capacity $c_{w}$; (2) time period $e_{r}-t_{r}$ for each request; (3) requests release time duration; (4) the number of workers. We choose the metrics requiring evaluation: (1) the number of invoking shortest arrival time queries query (); (2) insertion time; (3) response time; (4) memory cost. The bottleneck of time-dependent insertion is the shortest arrival time query over

Figure 9: Results of varying capacity of the worker
the time-dependent road network, and we aim to improve efficiency by avoiding invoking a large number of query (). In terms of the insertion time, for Cubic Time Algorithm and Quadratic Time Algorithm, it indicates the average time required to check the feasibility and calculate the increased travel time for each possible $(i, j)$ pair. For Linear Time Algorithm, it represents the average time for each $j$ value to check the feasibility, find the optimal $i$, and then calculate the increased travel time. Response time and memory cost are both commonly used metrics in many shared mobility applications [18, 25, 35]. Response time is the average time required to assign each request. Memory cost for Cubic Time Algorithm is for storing the worker's route, while for Quadratic Time Algorithm and Linear Time Algorithm, it is dominated by maintained compound travel functions and auxiliary arrays.

The kinetic [18] and GreedyDP [35] are specifically designed for static road networks and cannot satisfy all the constraints outlined in Definition 4 under real-world road conditions. To adapt them for use in time-dependent road networks, we modify them by using query () to check the feasibility and calculate the arrival time of each vertex in a new possible route, and the number of invoking query () is reported. Ref. [18, 35] use the response time as the metric of these methods, we report the response time to show the efficiency. Memory cost is omitted, as these methods use only a few auxiliary arrays (e.g., lower than 13 MB in our test).
Implementation. The experiments are conducted on a server with $40 \operatorname{Intel}(\mathrm{R}) \operatorname{Xeon}(\mathrm{R}) \mathrm{E} 52.30 \mathrm{GHz}$ processors with hyper-threading enabled and 128 GB memory. The algorithms are implemented in GNU C++. Each experiment is repeated 10 times and the average results are reported.

### 4.2 Experimental Results

Impact of Capacity of Workers. Fig. 9 shows the impact of worker's capacity on three datasets. Compared to baseline methods, Linear Time Algorithm invokes the shortest arrival time queries much less ( $75.24 \%-97.72 \%$ reduction), demonstrating the effectiveness of the compound travel function. Linear Time Algorithm also has the fastest insertion time (up to $44.5 \times$ faster on Cainiao than Cubic Time Algorithm) and reduces memory cost by $90.8 \%-98.7 \%$ compared to Quadratic Time Algorithm. As capacity increases, time and memory costs increase, but Linear Time Algorithm consistently has the lowest time cost and much lower memory cost (no more than 45 KB on Chengdu) than Quadratic Time Algorithm. Note that the insertion time and response time of Cubic Time Algorithm, and the memory cost of Quadratic Time Algorithm increase significantly due to time and space complexity.
Impact of Time $e_{r}-t_{r}$. Fig. 10 shows the results of varying the deadline of requests on Haikou and Chengdu. The values of $e_{r}-t_{r}$ are the scale values of the x-axis. Linear Time Algorithm outperforms others in terms of efficiency, which is up to $16.96 \times$ faster in response time. As $e_{r}-t_{r}$ increases, requests have larger deadlines, more requests can be inserted into the original route, and the time cost of Cubic Time Algorithm and space cost of Quadratic Time Algorithm increase significantly. Compared to the method with $O(n)$ space cost, Linear Time Algorithm consumes slightly higher memory (no more than 1 MB , which is acceptable).
Impact of Requests Release Time Duration. Fig. 11 shows the impact of release time duration on Cainiao and Chengdu. Linear Time Algorithm remains the fastest method with significantly fewer query () invocations (6.21-570.60× fewer) and faster response

Figure 10: Results of varying $e_{r}-t_{r}$

Figure 11: Results of varying requests release time duration
time (6.09-15.78× faster) than baselines on both datasets. As release time duration increases, the number of requests increases, and time cost increases for all algorithms. The memory cost of Linear Time Algorithm increases slightly.
Impact of Changes in Road Conditions. In reality, road conditions can change due to various reasons. We test the performances of the proposed methods under this setting. We randomly changed $10 \%$ of the road conditions in the road networks during algorithm testing, following the procedures in [37]. Whenever the road conditions change, we update the index supporting the query () as introduced in [37], then the worker's route and the data summary are updated. The results on Cainiao and Haikou are reported in Fig. 12, Linear Time Algorithm remains the fastest.

(a) Number of query on Cainiao

(c) Response time on Cainiao

of road conditions change

(b) Memory cost

## Figure 13: Results of scalability test on Cainiao

Scalability Test. We also conduct a scalability test on Cainiao with $10 k$ workers and requests of the entire day. Fig. 13 shows the response time and memory cost. Due to the page limitation, please refer to our full paper [6] for detailed results.
Computation Cost of $\operatorname{ComTravel}()$. Table 7 presents the average computation time of the compound travel function for each new route, it is included in the response time of each request. Results are reported for both default and maximum capacity settings, where more capacity leads to longer routes and more complex functions. The results demonstrate the efficiency and effectiveness of the designed compound travel function.

Table 7: Cost of ComTravel() for Linear Time Algo.

|  | Haikou |  | Chengdu |  | Cainiao |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Worker's capacity $c_{w}$ | 5 | 20 | 5 | 20 | 100 | 160 |
| Computation time $(m s)$ | 6.50 | 11.79 | 59.43 | 179.46 | 9.72 | 14.42 |
| Occupy ration to Response time | $28 \%$ | $34 \%$ | $9 \%$ | $12 \%$ | $22 \%$ | $26 \%$ |

Case Study: Benefits of Time-Dependent Networks. Timedependent road networks exhibit predictable characteristics, enabling foresight and prediction of future road network changes during route planning [20, 46]. Our experiments show that existing methods for insertion operations are not always optimal in realistic
dynamic settings. Static road networks cause $27 \%$ of requests to miss their deadlines, reducing the number of served requests compared to time-dependent road networks. For detailed experiment settings and results, please refer to our full paper [6].
Summary of Experiments. After conducting extensive experiments, we summarize the results as follows:

- It is impractical to extend the existing insertion operator straightforwardly to the time-dependent road networks. None of the baselines are more efficient than the $O\left(n^{2}\right)$ time algorithm. The baseline method takes more than 11,300 milliseconds to respond to one request on Chengdu and more than 890 milliseconds to respond to one request on Cainiao. Therefore, it is inefficient to handle large-scale requests from real-world shared mobility services.
- Our optimized algorithms, Quadratic Time Algorithm and Linear Time Algorithm, are 2.16-25.67× faster for Ride sharing and 6.39-44.5× faster for Logistics compared to baselines, due to their improvement in time complexity.
- Linear Time Algorithm reduces memory cost by up to $97.1 \%$ compared with Quadratic Time Algorithm. The memory consumed by Linear Time Algorithm is only slightly larger than Cubic Time Algorithm for both Ridesharing and Logistics services, e.g., no more than 77 KB on Chengdu.

## 5 RELATED WORK

Route processing over time-dependent road networks. The time-dependent road network has attracted many research efforts in spatial databases. To model dynamic traffic in reality, piecewise linear functions are widely adopted to fit the edge weight functions [ $9,37,38]$. Novel indexes are introduced in [15, 37] to answer route planning queries. Ref. [15] proposes a dual-level path index and utilizes a filter-and-refine strategy to enhance efficiency. Ref. [37] splits the road network into hierarchical partitions and constructs a balanced tree index, then computes the travel cost functions of border vertexes in partitions to answer queries.

Route planning over time-dependent road networks is another critical problem. Ref. [9] proposes an online route planning problem and develops a request-inserted algorithm to reduce the competitive ratio. However, it assumes that all passengers have the same destination. In [14], the last mile delivery problem is extended to time-dependent road networks, where a courier takes multiple parcels starting from the same warehouse, and each parcel can be delivered to alternative locations depending on the time. An insertion based method is proposed to heuristically insert the delivery location into the courier's path to maximize the number of delivered parcels. The existing works make the assumption that all passengers have the same destination or parcels have the same origin. In contrast, our time-dependent insertion problem is more challenging as it requires a feasible route, including both the origin and destination of each request. As shown in example 1, a new feasible route including both the origin $o_{3}$ and destination $d_{3}$ is planned to serve the new request $r_{3}$. Furthermore, [9] and [14] omit to check the feasibility of the worker. Therefore, existing algorithms cannot be applied to our problem.

Route planning for shared mobility. The shared mobility service has also been studied in many domains varying from Database
to AI. Different studies focus on different objectives, [22, 25] focus on maximizing the number of requests served, while [11, 17, 18, 29, 39] focus on minimizing the total travel time. Additionally, from the platform's perspective, the total revenue is also an objective that needs to be taken into consideration, as shown in [48, 49]. Based on the HST index [44], the route planning algorithms for the last-mile delivery are proposed [43, 45].

The insertion operator is an efficient method for planning new routes by inserting a new request into a worker's current route, as proposed in [32]. Recent studies have demonstrated its effectiveness and efficiency in large-scale static road networks [35, 39, 40]. Ref. [39, 40] extensively studied the insertion operator and developed a dynamic programming-based partition framework that reduces time complexity from $O\left(n^{3}\right)$ to $O\left(n^{2}\right)$, and further reduces it to $O(n)$ using a fenwick tree index. In [35], a unified route planning problem for shared mobility is defined, and a novel two-phased solution based on dynamic programming insertion is proposed to solve it approximately. However, these solutions do the calculations following additivity property of the static road networks, none of them consider the time-varying travel cost characteristics of road networks in real-world applications.

## 6 CONCLUSION

In this paper, we first study a real-time insertion operator for shared mobility on time-dependent road networks. A novel data summary model is designed to support the delay time query along the worker's route. The model is built by computing the compound travel functions between vertices of the route. By leveraging the query, we can reduce the time complexity of the existing insertion operator extended to the dynamic scenario from $O\left(n^{3}\right)$ to $O\left(n^{2}\right)$. Furthermore, we achieve an insertion operator with linear time and space cost by exploiting the FIFO property of a time-dependent road network. Specifically, we prove that given a position to insert the destination, we can find the optimal position to insert the origin of the new request in $O(1)$ time. Extensive experiments on datasets from different real-world applications demonstrate the efficiency and scalability of our time-dependent insertion operator. In particular, our proposed insertion operator can be up to 44.5 times faster than the baseline method under different settings on three real-world datasets.
